Timed Efficient Stream Loss-Tolerant Authentication (TESLA):  
Multicast Source Authentication Transform Introduction

Status of This Memo

This memo provides information for the Internet community. It does not specify an Internet standard of any kind. Distribution of this memo is unlimited.

Abstract

This document introduces Timed Efficient Stream Loss-tolerant Authentication (TESLA). TESLA allows all receivers to check the integrity and authenticate the source of each packet in multicast or broadcast data streams. TESLA requires no trust between receivers, uses low-cost operations per packet at both sender and receiver, can tolerate any level of loss without retransmissions, and requires no per-receiver state at the sender. TESLA can protect receivers against denial of service attacks in certain circumstances. Each receiver must be loosely time-synchronized with the source in order to verify messages, but otherwise receivers do not have to send any messages. TESLA alone cannot support non-repudiation of the data source to third parties.

This informational document is intended to assist in writing standardizable and secure specifications for protocols based on TESLA in different contexts.

## 1. Introduction

In multicast, a single packet can reach millions of receivers. Unfortunately, this introduces the danger that an attacker can potentially also reach millions of receivers with a malicious packet. Through source authentication, receivers can ensure that a received multicast packet originates from the correct source. In these respects, a multicast is equivalent to a broadcast to a superset of the multicast receivers.

In unicast communication, we can achieve data authentication through a simple mechanism: the sender and the receiver share a secret key to compute a message authentication code (MAC) of all communicated data. When a message with a correct MAC arrives, the receiver is assured that the sender generated that message. Standard mechanisms achieve unicast authentication this way; for example, TLS or IPsec [1,2].

Symmetric MAC authentication is not secure in a broadcast setting. Consider a sender that broadcasts authentic data to mutually mistrusting receivers. The symmetric MAC is not secure: every receiver knows the MAC key and therefore could impersonate the sender and forge messages to other receivers. Intuitively, we need an asymmetric mechanism to achieve authenticated broadcast, such that

every receiver can verify the authenticity of messages it receives, without being able to generate authentic messages. Achieving this in an efficient way is a challenging problem [3].

The standard approach to achieving such asymmetry for authentication is to use asymmetric cryptography; e.g., a digital signature. Digital signatures have the required asymmetric property: the sender generates the signature with its private key, and all receivers can verify the signature with the sender's public key, but a receiver with the public key alone cannot generate a digital signature for a new message. A digital signature provides non-repudiation, a stronger property than authentication. However, digital signatures have a high cost: they have a high computation overhead for both the sender and the receiver, and most signatures also have a high-bandwidth overhead. Since we assume broadcast settings for which the sender does not retransmit lost packets, and the receiver still wants to authenticate each packet it receives immediately, we would need to attach a digital signature to each message. Because of the high overhead of asymmetric cryptography, this approach would restrict us to low-rate streams, and to senders and receivers with powerful workstations. We can try to amortize one digital signature over multiple messages. However, this approach is still expensive in contrast to symmetric cryptography, since symmetric cryptography is in general 3 to 5 orders of magnitude more efficient than asymmetric cryptography. In addition, the straight-forward amortization of one digital signature over multiple packets requires reliability, as the receiver needs to receive all packets to verify the signature. A number of schemes that follow this approach are [4,5,6,7]. See [8] for more details.

This document presents the Timed Efficient Stream Loss-tolerant Authentication protocol (TESLA). TESLA uses mainly symmetric cryptography, and uses time-delayed key disclosure to achieve the required asymmetry property. However, TESLA requires loosely synchronized clocks between the sender and the receivers. See more details in Section 3.3.1. Schemes that follow a similar approach to TESLA are [9,10,11].

### 1.1. Notation

To denote the subscript or an index of a variable, we use the underscore between the variable name and the index; e.g., the key  $K$  with index  $i$  is  $K_i$ , and the key  $K$  with index  $i+d$  is  $K_{i+d}$ . To write a superscript, we use the caret; e.g., function  $F$  with the argument  $x$  executed  $i$  times is  $F^i(x)$ .

## 2. Functionality

TESLA provides delayed per-packet data authentication and integrity checking. The key idea to providing both efficiency and security is a delayed disclosure of keys. The delayed key disclosure results in an authentication delay. In practice, the delay is on the order of one RTT (round-trip-time).

TESLA has the following properties:

- o Low computation overhead for generation and verification of authentication information.
- o Low communication overhead.
- o Limited buffering required for the sender and the receiver, and therefore timely authentication for each individual packet.
- o Strong robustness to packet loss.
- o Scales to a large number of receivers.
- o Protects receivers from denial of service attacks in certain circumstances if configured appropriately.
- o Each receiver cannot verify message authenticity unless it is loosely time-synchronized with the source, where synchronization can take place at session setup. Once the session is in progress, receivers need not send any messages or acknowledgements.
- o Non-repudiation is not supported; each receiver can know that a stream is from an authentic source, but cannot prove this to a third party.

TESLA can be used in the network layer, in the transport layer, or in the application layer. Delayed authentication, however, requires buffering of packets until authentication is completed. Certain applications intolerant of delay may be willing to process packets in parallel to being buffered while awaiting authentication, as long as roll-back is possible if packets are later found to be unauthenticated. For instance, an interactive video may play out packets still awaiting authentication, but if they are later found to be unauthenticated, it could stop further play-out and warn the viewer that the last x msec were unauthenticated and should be ignored. However, in the remainder of this document, for brevity, we will assume that packets are not processed in parallel to buffering.

## 2.1. Threat Model and Security Guarantee

We design TESLA to be secure against a powerful adversary with the following capabilities:

- o Full control over the network. The adversary can eavesdrop, capture, drop, re-send, delay, and alter packets.
- o Access to a fast network with negligible delay.
- o The adversary's computational resources may be very large, but not unbounded. In particular, this means that the adversary can perform efficient computations, such as computing a reasonable number of pseudo-random function applications and MACs with negligible delay. Nonetheless, the adversary cannot find the key of a pseudo-random function (or distinguish it from a random function) with non-negligible probability.

The security property of TESLA guarantees that the receiver never accepts  $M_i$  as an authentic message unless the sender really sent  $M_i$ . A scheme that provides this guarantee is called a secure broadcast authentication scheme.

Because TESLA expects the receiver to buffer packets before authentication, the receiver needs to protect itself from a potential denial of service (DoS) attack due to a flood of bogus packets (see Section 3.8).

## 2.2. Assumptions

TESLA makes the following assumptions in order to provide security:

1. The sender and the receiver must be loosely time-synchronized. Specifically, each receiver must be able to compute an upper bound on the lag of the receiver clock relative to the sender clock. We denote this quantity with  $D_t$ . (That is,  $D_t = \text{sender time} - \text{receiver time}$ ). We note that an upper bound on  $D_t$  can easily be obtained via a simple two-message exchange. (Such an exchange can be piggybacked on any secure session initiation protocol. Alternatively, standard protocols such as NTP [15] can be used.
2. TESLA MUST be bootstrapped at session setup through a regular data authentication system. One option is to use a digital signature algorithm for this purpose, in which case the receiver is required to have an authentic copy of either the sender's public key certificate or a root key certificate in

case of a PKI (public-key infrastructure). Alternatively, this initialization step can be done using any secure session initiation protocol.

3. TESLA uses cryptographic MAC and PRF (pseudo-random functions). These MUST be cryptographically secure. Further details on the instantiation of the MAC and PRF are in Section 3.4.

We would like to emphasize that the security of TESLA does NOT rely on any assumptions about network propagation delay.

### 3. The Basic TESLA Protocol

TESLA is described in several academic publications: A book on broadcast security [12], a journal paper [13], and two conference papers [7,14]. Please refer to these publications for in-depth proofs of security, experimental results, etc.

We first outline the main ideas behind TESLA.

#### 3.1. Protocol Sketch

As we argue in the introduction, broadcast authentication requires a source of asymmetry. TESLA uses time for asymmetry. We first make sure that the sender and receivers are loosely time-synchronized as described above. Next, the sender forms a one-way chain of keys, in which each key in the chain is associated with a time interval (say, a second). Here is the basic approach:

- o The sender attaches a MAC to each packet. The MAC is computed over the contents of the packet. For each packet, the sender uses the current key from the one-way chain as a cryptographic key to compute the MAC.
- o The sender discloses a key from the one-way chain after some pre-defined time delay (e.g., the key used in time interval  $i$  is disclosed at time interval  $i+3$ ).
- o Each receiver receives the packet. Each receiver knows the schedule for disclosing keys and, since it has an upper bound on the local time at the sender, it can check that the key used to compute the MAC was not yet disclosed by the sender. If it was not, then the receiver buffers the packet. Otherwise the packet is dropped due to inability to authenticate. Note that we do not know for sure whether a "late packet" is a bogus one or

simply a delayed packet. We drop the packet because we are unable to authenticate it. (Of course, an implementation may choose not to drop packets and to use them unauthenticated.)

- o Each receiver checks that the disclosed key belongs to the hash-chain (by checking against previously released keys in the chain) and then checks the correctness of the MAC. If the MAC is correct, the receiver accepts the packet.

Note that one-way chains have the property that if intermediate values of the one-way chain are lost, they can be recomputed using subsequent values in the chain. Even if some key disclosures are lost, a receiver can recover the corresponding keys and check the correctness of earlier packets.

We now describe the stages of the basic TESLA protocol in this order: sender setup, receiver bootstrap, sender transmission of authenticated broadcast messages, and receiver authentication of broadcast messages.

### 3.2. Sender Setup

The sender divides the time into uniform intervals of duration  $T_{int}$ . The sender assigns one key from the one-way chain to each time interval in sequence.

The sender determines the length  $N$  of the one-way chain  $K_0, K_1, \dots, K_N$ , and this length limits the maximum transmission duration before a new one-way chain must be created. The sender picks a random value for  $K_N$ . Using a pseudo-random function (PRF),  $f$ , the sender constructs the one-way function  $F: F(k) = f_k(0)$ . The rest of the chain is computed recursively using  $K_i = F(K_{i+1})$ . Note that this gives us  $K_i = F^{N-i}(K_N)$ , so the receiver can compute any value in the key chain from  $K_N$ , even if it does not have intermediate values. The key  $K_i$  will be used to authenticate packets sent in time interval  $i$ .

Jakobsson [20] and Coppersmith and Jakobsson [21] present a storage- and computation-efficient mechanism for one-way chains. For a chain of length  $N$ , storage is about  $\log(N)$  elements, and the computation overhead to reconstruct each element is also about  $\log(N)$ .

The sender determines the duration of a time interval,  $T_{int}$ , and the key disclosure delay,  $d$ . ( $T_{int}$  is measured in time units, say milliseconds, and  $d$  is measured in number of time intervals. That is, a key that is used for time interval  $i$  will be disclosed in time interval  $i+d$ .) It is stressed that the scheme remains secure for any values of  $T_{int}$  and  $d > 0$ . Still, correct choice of  $T_{int}$  and  $d$  is

crucial for the usability of the scheme. The choice is influenced by the estimated network delay, the length of the transmission, and the tolerable delay at the receiver. A  $T_{int}$  that is too short will cause the keys to run out too soon. A  $T_{int}$  that is too long will cause excessive delay in authentication for some of the packets (those that were sent at the beginning of a time period). A delay  $d$  that is too short will cause too many packets to be unverifiable by the receiver. A delay  $d$  that is too long will cause excessive delay in authentication.

The sender estimates a reasonable upper bound on the network delay between the sender and any receiver as  $m$  milliseconds. This includes any delay expected in the stack (see Section 4, on layer placement). If the sender expects to send a packet every  $n$  milliseconds, then a reasonable value for  $T_{int}$  is  $\max(n,m)$ . Based on  $T_{int}$ , a rule of thumb for determining the key disclosure delay,  $d$ , is given in Section 3.6.

The above value for  $T_{int}$  is neither an upper or a lower bound; it is merely the value that reduces key change processing to a minimum without causing authentication delay to be higher than necessary. If the application can tolerate higher authentication delay, then  $T_{int}$  can be made appropriately larger. Also, if  $m$  (or  $n$ ) increases during the session, perhaps due to congestion or a late joiner on a high delay path,  $T_{int}$  need not be revised.

Finally, the sender needs to allow each receiver to synchronize its time with the sender. See more details on how this can be done in Section 3.3.1. (It is stressed that estimating the network delay is a separate task from the time synchronization between the sender and the receivers.)

### 3.3. Bootstrapping Receivers

Before a receiver can authenticate messages with TESLA, it needs to have the following:

- o An upper bound,  $D_t$ , on the lag of its own clock with respect to the clock of the sender. (That is, if the local time reading is  $t$ , the current time reading at the sender is at most  $t+D_t$ .)
- o One authenticated key of the one-way key chain. (Typically, this will be the last key in the chain; i.e.,  $K_0$ . This key will be signed by the sender, and all receivers will verify the signature with the public key of the signer.)

- o The disclosure schedule of the following keys:
  - $T_{int}$ , the interval duration.
  - $T_0$ , the start time of interval 0.
  - $N$ , the length of the one-way key chain.
  - $d$ , the key disclosure delay  $d$  (in number of intervals).

The receiver can perform the time synchronization and get the authenticated TESLA parameters in a two-round message exchange, as described below. We stress again that time synchronization can be performed as part of the registration protocol between any receiver (including late joiners) and the sender, or between any receiver and a group controller.

### 3.3.1. Time Synchronization

Various approaches exist for time synchronization [15,16,17,18]. TESLA only requires the receiver to know an upper bound on the delay of its local clock with respect to the sender's clock, so a simple algorithm is sufficient. TESLA can be used with direct, indirect, and delayed synchronization as three default options. The specific synchronization method will be part of each instantiation of TESLA.

For completeness, we sketch a simple method for direct synchronization between the sender and a receiver:

- o The receiver sends a (sync  $t_r$ ) message to the sender and records its local time,  $t_r$ , at the moment of sending.
- o Upon receipt of the (sync  $t_r$ ) message, the sender records its local time,  $t_s$ , and sends (synch,  $t_r, t_s$ ) to the receiver.
- o Upon receiving (synch,  $t_r, t_s$ ), the receiver sets  $D_t = t_s - t_r + S$ , where  $S$  is an estimated bound on the clock drift throughout the duration of the session.

Note:

- o Assuming that the messages are authentic (i.e., the message received by the receiver was actually sent by the sender), and assuming that the clock drift is at most  $S$ , then at any point throughout the session  $T_s < T_r + D_t$ , where  $T_s$  is the current time at the sender and  $T_r$  is the current time at the receiver.
- o The exchange of sync messages needs to be authenticated. This can be done in a number of ways; for instance, with a secure NTP protocol or in conjunction with a session set-up protocol.

For indirect time synchronization (e.g., synchronization via a group controller), the sender and the controller engage in a protocol for finding the value  $D^0_t$  between them. Next, each receiver,  $R$ , interacts with the group controller (say, when registering to the group) and finds the value  $D^R_t$  between the group controller and  $R$ . The overall value of  $D_t$  within  $R$  is set to the sum  $D_t = D^R_t + D^0_t$ .

### 3.4. Broadcasting Authenticated Messages

Each key in the one-way key chain corresponds to a time interval. Every time a sender broadcasts a message, it appends a MAC to the message, using the key corresponding to the current time interval. The key remains secret for the next  $d-1$  intervals, so messages that a sender broadcasts in interval  $j$  effectively disclose key  $K_{j-d}$ . We call  $d$  the key disclosure delay.

We do not want to use the same key multiple times in different cryptographic operations; that is, using key  $K_j$  to derive the previous key of the one-way key chain  $K_{j-1}$ , and using the same key  $K_j$  as the key to compute the MACs in time interval  $j$  may potentially lead to a cryptographic weakness. Using a pseudo-random function (PRF),  $f'$ , we construct the one-way function  $F'$ :  $F'(k) = f'_k(1)$ . We use  $F'$  to derive the key to compute the MAC of messages in each interval. The sender derives the MAC key as follows:  $K'_i = F'(K_i)$ . Figure 1 depicts the one-way key chain construction and MAC key derivation. To broadcast message  $M_j$  in interval  $i$  the sender constructs the packet

$$P_j = \{M_j \parallel i \parallel \text{MAC}(K'_i, M_j) \parallel K_{\{i-d\}}\}$$

where  $\parallel$  denotes concatenation.

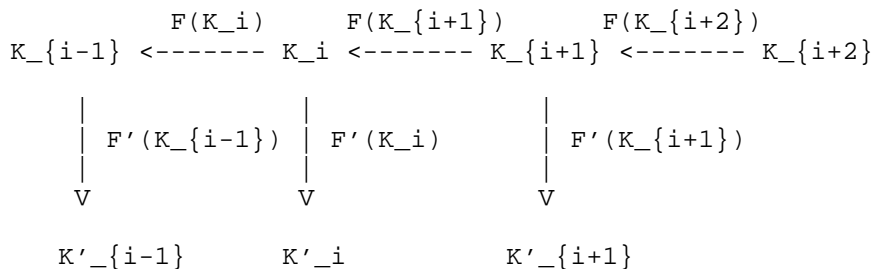

Figure 1: At the top of the figure, we see the one-way key chain (derived using the one-way function  $F$ ), and the derived MAC keys (derived using the one-way function  $F'$ ).

### 3.5. Authentication at Receiver

Once a sender discloses a key, we must assume that all parties might have access to that key. An adversary could create a bogus message and forge a MAC using the disclosed key. So whenever a packet arrives, the receiver must verify that the MAC is based on a safe key; a safe key is one that is still secret (known only by the sender). We define a safe packet or safe message as one with a MAC that is computed with a safe key.

If a packet proves safe, it will be buffered, only to be released when its own key, disclosed in a later packet, proves its authenticity. Although a newly arriving packet cannot immediately be authenticated, it may disclose a new key so that earlier, buffered packets can be authenticated. Any newly disclosed key must be checked to determine whether it is genuine; then authentication of buffered packets that have been waiting for it can proceed.

We now describe TESLA authentication at the receiver with more detail, listing all of these steps in the exact order they should be carried out:

1. Safe packet test: When the receiver receives packet  $P_j$ , which carries an interval index  $i$ , and a disclosed key  $K_{\{i-d\}}$ , it first records local time  $T$  at which the packet arrived. The receiver then computes an upper bound  $t_j$  on the sender's clock at the time when the packet arrived:  $t_j = T + D_t$ . To test whether the packet is safe, the receiver then computes the highest interval  $x$  the sender could possibly be in; namely  $x = \text{floor}((t_j - T_0) / T_{\text{int}})$ . The receiver verifies that  $x < i + d$  (where  $i$  is the interval index), which implies that the sender is not yet in the interval during which it discloses the key  $K_i$ .

Even if the packet is safe, the receiver cannot yet verify the authenticity of this packet sent in interval  $i$  without key  $K_i$ , which will be disclosed later. Instead, it adds the triplet  $(i, M_j, \text{MAC}(K'_i, M_j))$  to a buffer and verifies the authenticity after it learns  $K'_i$ .

If the packet is unsafe, then the receiver considers the packet unauthenticated. It should discard unsafe packets, but, at its own risk it may choose to use them unverified.

2. New key index test: Next the receiver checks whether a key  $K_v$  has already been disclosed with the same index  $v$  as the current disclosed key  $K_{\{i-d\}}$ , or with a later one; that is, with  $v \geq i-d$ .

3. Key verification test: If the disclosed key index is new, the receiver checks the legitimacy of  $K_{i-d}$  by verifying, for some earlier disclosed key  $K_v$  ( $v < i-d$ ), that  $K_v = F^{i-d-v}(K_{i-d})$ .

If key verification fails, the newly arrived packet  $P_j$  should be discarded.

4. Message verification tests: If the disclosed key is legitimate, the receiver then verifies the authenticity of any earlier safe, buffered packets of interval  $i-d$ . To authenticate one of the buffered packets  $P_h$  containing message  $M_h$  protected with a MAC that used key index  $i-d$ , the receiver will compute  $K'_{i-d} = F'(K_{i-d})$  from which it can compute  $MAC(K'_{i-d}, M_h)$ .

If this MAC equals the MAC stored in the buffer, the packet is authenticated and can be released from the buffer. If the MACs do not agree, the buffered packet  $P_h$  should be discarded.

The receiver continues to verify and release (or not) any remaining buffered packets that depend on the newly disclosed key  $K_{i-d}$ .

Using a disclosed key, we can calculate all previous disclosed keys, so even if packets are lost, we will still be able to verify buffered, safe packets from earlier time intervals. Thus, if  $i-d-v > 1$ , the receiver can also verify the authenticity of the stored packets of intervals  $v+1 \dots i-d-1$ .

### 3.6. Determining the Key Disclosure Delay

An important TESLA parameter is the key disclosure delay  $d$ . Although the choice of the disclosure delay does not affect the security of the system, it is an important performance factor. A short disclosure delay will cause packets to lose their safety property, so receivers will not be able to authenticate them; but a long disclosure delay leads to a long authentication delay for receivers. We recommend determining the disclosure delay as follows: In direct time synchronization, let the RTT,  $2m$ , be a reasonable upper bound on the round trip time between the sender and any receiver including worst-case congestion delay and worst-case buffering delay in host stacks. Then choose  $d = \text{ceil}(2m / T_{\text{int}}) + 1$ . Note that rounding up the quotient ensures that  $d \geq 2$ . Also note that a disclosure delay of one time interval ( $d=1$ ) does not work. Consider packets sent close to the boundary of the time interval: After the network propagation delay and the receiver time synchronization error, a

receiver will not be able to authenticate the packet, because the sender will already be in the next time interval when it discloses the corresponding key.

Measuring the delay to each receiver before determining  $m$  will still not adequately predict the upper bound on delay to late joiners, or where congestion delay rises later in the session. It may be adequate to use a hard-coded historic estimate of worst-case delay (e.g., round trip delays to any host on the intra-planetary Internet rarely exceed 500msec if routing remains stable).

We stress that the security of TESLA does not rely on any assumptions about network propagation delay: If the delay is longer than expected, then authentic packets may be considered unauthenticated. Still, no inauthentic packet will be accepted as authentic.

### 3.7. Denial of Service Protection

Because TESLA authentication is delayed, receivers seem vulnerable to flooding attacks that cause them to buffer excess packets, even though they may eventually prove to be inauthentic. When TESLA is deployed in an environment with a threat of flooding attacks, the receiver can take a number of extra precautions.

First, we list simple DoS mitigation precautions that can and should be taken by any receiver independently of others, thus requiring no changes to the protocol or sender behaviour. We precisely specify where these extra steps interleave with the receiver authentication steps already given in Section 3.5.

- o Session validity test: Before the safe packet test (Step 1), check that arriving packets have a valid source IP address and port number for the session, that they do not replay a message already received in the session, and that they are not significantly larger than the packet sizes expected in the session.
- o Reasonable misordering test: Before the key verification test (Step 3), check whether the disclosed key index  $i-d$  of the arriving packet is within  $g$  of the previous highest disclosed key index  $v$ ; thus, for example,  $i-d-v \leq g$ .  $g$  sets the threshold beyond which an out-of-order key index is assumed to be malicious rather than just misordered. Without this test, an attacker could exploit the iterated test in Step 3 to make receivers consume inordinate CPU time checking along the hash chain for what appear to be extremely misordered packets.

Each receiver can independently adapt  $g$  to prevailing attack conditions; for instance, by using the following algorithm. Initially,  $g$  should be set to  $g_{\max}$  (say, 16). But whenever an arriving packet fails the reasonable misordering test above or the key verification test (Step 3),  $g$  should be dropped to  $g_{\min}$  ( $>0$  and typically 1). At each successful key verification (Step 3),  $g$  should be incremented by 1 unless it is already  $g_{\max}$ . These precautions will guarantee that sustained attack packets cannot cause the receiver to execute more than an average of  $g_{\min}$  hashes each, unless they are paced against genuine packets. In the latter case, attacks are limited to  $g_{\max}/(g_{\max}-g_{\min})$  hashes per each genuine packet.

When choosing  $g_{\max}$  and  $g_{\min}$ , note that they limit the average gap in a packet sequence to  $g \cdot \max(n,m)/n$  packets (see Section 3.2 for definitions of  $n$  and  $m$ ). So with  $g=1$ ,  $m=100\text{msec RTT}$ , and  $n=4\text{msec inter-packet period}$ , reordering would be limited to gaps of 25 packets on average. Bigger naturally occurring gaps would have to be written off as if they were losses.

Stronger DoS protection requires that both senders and receivers arrange additional constraints on the protocol. Below, we outline three alternative extensions to basic TESLA; the first adding group authentication, the second not re-using keys during a time interval, and the third moving buffering to the sender.

It is important to understand the applicability of each scheme, as the first two schemes use slightly more (but bounded) resources in order to prevent attackers from consuming unbounded resources. Adding group authentication requires larger per-packet overhead. Never re-using a key requires both ends to process two hashes per packet (rather than per time interval), and the sender must store or re-generate a longer hash chain. The merits of each scheme, summarised after each is described below, must be weighed against these additional costs.

#### 3.7.1. Additional Group Authentication

This scheme simply involves addition of a group MAC to every packet. That is, a shared key  $K_g$  common to the whole group is communicated as an additional step during receiver bootstrap (Section 3.3). Then, during broadcast of message  $M_j$  (Section 3.4), the sender computes the group MAC of each packet  $\text{MAC}(K_g, P_j)$ , which it appends to the packet header. Note that the group MAC covers the whole packet  $P_j$ ; that is, the concatenation of the message  $M_j$  and the additional TESLA authentication material, using the formula in Section 3.4.

Immediately upon packet arrival, each receiver can check that each packet came from a group member, by recomputing and comparing the group MAC.

Note that TESLA source authentication is only necessary when other group members cannot be trusted to refrain from spoofing the source; otherwise, simpler group authentication would be sufficient. Therefore, additional group authentication will only make sense in scenarios where other group members are trusted to refrain from flooding the group, but where they are still not trusted to refrain from spoofing the source.

### 3.7.2. Not Re-using Keys

In TESLA as described so far, each MAC key was used repeatedly for all the packets sent in a time interval. If instead the sender were to guarantee never to use a MAC key more than once, each disclosed key could assume an additional purpose on top of authenticating a previously buffered packet. Each key would also immediately show each receiver that the sender of each arriving packet knew the next key back along the hash chain, which is now only disclosed once, similar to S/KEY [22]. Therefore a reasonable receiver strategy would be to discard any arriving packets that disclosed a key seen already. The fill rate of the receiver's buffer would then be clocked by each packet revealed by the genuine sender, preventing memory flooding attacks.

An attacker with control of a network element or of a faster bypass network could intercept messages and overtake or replace them with different messages but with the same keys. However, as long as packets are only buffered if they also pass the delay safety test, these bogus packets will fail TESLA verification after the disclosure delay. Admittedly, receivers could be fooled into discarding genuine messages that had been overtaken by bogus ones. But it is hard to overtake messages without compromising a network element, and any attacker that can compromise a network element can discard genuine messages anyway. We will now describe this scheme in more detail.

For the sender, the scheme is hardly different from TESLA. It merely uses an interval duration short enough to ensure a new key back along the hash chain for each packet. So the rule of thumb given in Section 3.2 for an efficient re-keying interval  $T_{int}$  no longer applies. Instead,  $T_{int}$  is simply  $n$ , the inter-arrival time between packets in milliseconds. The rule of thumb for calculating  $d$ , the key disclosure delay, remains unchanged from that given in Section 3.6.

If the packet rate is likely to vary, for safety  $n$  should be taken as the minimum inter-departure time between any two packets. (In fact,  $n$  need not be so strict; it can be the minimum average packet inter-departure time over any burst of  $d$  packets expected throughout the session.)

Note that if the packet rate slows down, whenever no packets are sent in a key change interval, the key index must increment along the hash chain once for each missed interval. (During a burst, if the less strict definition of  $n$  above has been used, packets may need to depart before their key change interval. The sender can safely continue changing the key for each packet, using keys from future key intervals, because if  $n$  has been chosen as defined above, such bursts will never sustain long enough to cause the associated key to be disclosed in a period less than the disclosure delay later.)

To be absolutely clear, the precise guarantees that the sender keeps to by following the above guidance are:

- o not to re-use a MAC key,
- o not to use a MAC key  $K_i$  after its time interval  $i$ , and
- o not to disclose key  $K_i$  sooner than the disclosure delay  $d * T_{int}$  following the packet it protects.

Sender setup, receiver bootstrapping, and broadcasting authenticated messages are otherwise all identical to the descriptions in Sections 3.2, 3.3, and 3.4, respectively. However, the following step must be added to the receiver authentication steps in Section 3.5:

- o After Step 2, if a packet arrives carrying a key index  $i-d$  that has already been received, it should not be buffered.

This simple scheme would suffice against DoS, were it not for the fact that a network sometimes misorders packets without being compromised. Even without control of a network element, an attacker can opportunistically exploit such openings to fool a receiver into buffering a bogus packet and discarding a later genuine one. A receiver can choose to set aside a fixed size cache and can manage it to minimise the chances of discarding a genuine packet. However, given such vulnerabilities are rare and unpredictable, it is simpler to count these events as additions to the network loss rate. As always, TESLA authentication will still uncover any bogus packets after the disclosure delay.

To summarise, avoiding re-using keys has the following properties, even under extreme flooding attacks:

- o After delayed TESLA authentication, packets arriving within the disclosure delay will always be identified as authentic if they are and as inauthentic if they are not authentic.
- o The fill rate of the receiver's buffer is clocked by each packet revealed by the genuine sender, preventing memory flooding attacks.
- o An attacker with control of a network element can cause any loss rate it chooses (but that's always true anyway).
- o Where attackers do not have control of any network elements, the effective loss rate is bounded by the sum of the network's actual loss rate and its re-ordering rate.

### 3.7.3. Sender Buffering

Buffering of packets can be moved to the sender side; then receivers can authenticate packets immediately upon receipt. This method is described in [14].

### 3.8. Some Extensions

Let us mention two salient extensions of the basic TESLA scheme. A first extension allows having multiple TESLA authentication chains for a single stream, where each chain uses a different delay for disclosing the keys. This extension is typically used to deal with heterogeneous network delays within a single multicast transmission. A second extension allows having most of the buffering of packets at the sender side (rather than at the receiver side). Both extensions are described in [14].

TESLA's requirement that a key be received in a later packet for authentication prevents a receiver from authenticating the last part of a message. Thus, to enable authentication of the last part of a message or of the last message before a transmission suspension, the sender needs to send an empty message with the key.

## 4. Layer Placement

TESLA authentication can be performed at any layer in the networking stack. Three natural places are the network, transport, or application layer. We list some considerations regarding the choice of layer:

- o Performing TESLA in the network layer has the advantage that the transport or application layer only receives authenticated data, potentially aiding a reliability protocol and mitigating denial

of service attacks. (Indeed, reliable multicast tools based on forward error correction are highly susceptible to denial of service due to bogus packets.)

- o Performing TESLA in either the transport or the application layer has the advantage that the network layer remains unchanged, but it has the potential drawback that packets are obtained by the application layer only after being processed by the transport layer. Consequently, if buffering is used in the transport, then this may introduce additional and unpredictable delays on top of the unavoidable network delays.
- o Note that because TESLA relies upon timing of packets, deploying TESLA on top of a protocol or layer that aggressively buffers packets and hides the true packet arrival time will significantly reduce TESLA's performance.

## 5. Security Considerations

See the academic publications on TESLA [7,13,19] for several security analyses. Regarding the security of implementations, by far the most delicate point is the verification of the timing conditions. Care should be taken to make sure that (a) the value bound  $D_t$  on the clock skew is calculated according to the spec at session setup and that (b) the receiver records the arrival time of the packet as soon as possible after the packet's arrival, and computes the safety condition correctly.

It should be noted that a change to the key disclosure schedule for a message stream should never be declared within the message stream itself. This would introduce a vulnerability, because a receiver that did not receive the notification of the change would still believe in the old key disclosure schedule.

Finally, in common with all authentication schemes, if verification is located separately from the ultimate destination application (e.g., an IPSec tunnel end point), a trusted channel must be present between verification and the application. For instance, the interface between the verifier and the application might simply assume that packets received by the application must have been verified by the verifier (because otherwise they would have been dropped). The application is then vulnerable to reception of packets that have managed to bypass the verifier.

## 6. Acknowledgements

We would like to thank the following for their feedback and support: Mike Luby, Mark Baugher, Mats Naslund, Dave McGrew, Ross Finlayson, Sylvie Laniece, Lakshminath Dondeti, Russ Housley, and the IESG reviewers.
